16  
17 **Abstract**

18 We investigate trapping of a nonwetting (NW) phase, air, within Bentheimer sandstone  
19 cores during drainage-imbibition flow experiments, as quantified on a three dimensional (3D)  
20 pore-scale basis via x-ray computed microtomography (x-ray CMT). The wetting (W) fluid in  
21 these experiments was deionized water doped with potassium iodide (1:6 by weight). We  
22 interpret these experiments based on the capillary-viscosity-gravity force dominance exhibited  
23 by the Bentheimer-air-brine system and compare to a wide range of previous drainage-imbibition  
24 experiments in different media and with different fluids. From this analysis, we conclude that  
25 viscous and capillary forces dominate in the Bentheimer-air-brine system as well as in the  
26 Bentheimer-supercritical CO<sub>2</sub>-brine system. In addition, we further develop the relationship  
27 between initial (post-drainage) NW phase connectivity and residual (post-imbibition) trapped  
28 NW phase saturation, while also taking into account initial NW phase saturation and imbibition  
29 capillary number. We quantify NW phase connectivity via a topological measure as well as by a  
30 statistical percolation metric. These metrics are evaluated for their utility and appropriateness in  
31 quantifying NW phase connectivity within porous media. Here, we find that there is a linear  
32 relationship between initial NW phase connectivity (as quantified by the normalized Euler  
33 number,  $\hat{\chi}$ ) and capillary trapping efficiency; for a given imbibition capillary number, capillary  
34 trapping efficiency (residual NW phase saturation normalized by initial NW phase saturation)

## 20 **1.0 Introduction**

21 During immiscible multiphase flow, drainage is the process of nonwetting (NW) fluid  
22  
23 invading the pore space and displacing wetting (W) fluid, and imbibition is the process of W  
24  
25 fluid invading the pore space and displacing NW fluid. Many engineered processes in the  
26  
27 subsurface require fundamental understanding of drainage and imbibition processes and the  
28  
29 resulting NW phase capillary trapping; for example, during oil recovery operations, remediation  
30  
31 of non-aqueous phase liquid (NAPL) contaminants in the subsurface, and geologic sequestration  
32  
33 of carbon dioxide (CO<sub>2</sub>). In these examples, water is generally assumed to be the W phase; while  
34  
35 oil, NAPL, or CO<sub>2</sub> are considered to be the NW phase. Although there are abundant exceptions  
36  
37 to this assumption (e.g. intermediate-wet or oil-wet media), in this work we refer to water as the  
38  
39 W phase for simplicity and consistency with previous work. In oil recovery and NAPL  
40  
41 remediation processes the system already exists in the *initial* (post-drainage) state, i.e. both water  
42  
43 and NW fluid (oil or NAPL) are already present in the system, and the bulk of previous research  
44  
45 has focused on how to alter the imbibition (water flood) process to mobilize the maximum  
46  
47 amount of trapped NW phase. Geologic CO<sub>2</sub> sequestration differs from oil recovery and NAPL  
48  
49 remediation processes because both the drainage (i.e. CO<sub>2</sub> injection) and imbibition (i.e. water  
50  
51 chase or groundwater flow) processes may be engineered, and the overall aim of the process is to  
52

1  
2  
3  
4 trap, rather than mobilize, NW phase in the pore space of the geologic medium. From a CO<sub>2</sub>  
5  
6 sequestration perspective, maximizing residual NW phase saturation is optimal; this is in  
7  
8 comparison to oil recovery or remediation processes, in which minimal NW phase is the optimal  
9  
10 residual state. Comparison between different studies and applications is complicated because  
11  
12 fluid properties (e.g. density, viscosity, interfacial tension), medium properties (grain and pore  
13  
14 size distributions, pore space connectivity, etc.), and flow properties (engineered injection or  
15  
16 natural groundwater flow rates) vary widely depending on the application in question.  
17  
18  
19  
20

21           Recent focus on CO<sub>2</sub> sequestration as a global climate change mitigation strategy has  
22  
23 prompted renewed study into the phenomena of capillary trapping in porous media (e.g. Juanes  
24  
25 et al. [1], Al Mansoori et al.[2], Akbarabadi and Piri [3], Andrew et al. [4], among others).  
26  
27  
28 Capillary trapping of CO<sub>2</sub>, wherein CO<sub>2</sub> is trapped by capillary forces in the pore bodies of a  
29  
30 porous medium, is a relatively secure form of trapping, as compared to “structural” or  
31  
32 “hydrodynamic” trapping, where the buoyant CO<sub>2</sub> is contained by an impermeable caprock; in  
33  
34 addition, capillary trapping occurs on relatively short timescales, as compared to dissolution  
35  
36 trapping or mineral trapping [5]. Thus, maximization of capillary trapping is important to ensure  
37  
38 a safe and stable geologic carbon sequestration operation. Previous work has investigated NW  
39  
40 phase capillary trapping over a wide range of fluid pairs, media types, and flow conditions for oil  
41  
42 recovery and NAPL remediation applications. The results of these studies could greatly enhance  
43  
44 fundamental knowledge that would benefit CO<sub>2</sub> sequestration studies if the results are  
45  
46 appropriately compared and characterized. CO<sub>2</sub> is in a supercritical state at sequestration  
47  
48 reservoir operations; relatively small variations in pressure, temperature, and salinity of the W  
49  
50 phase have significant effects on the CO<sub>2</sub> density, CO<sub>2</sub> viscosity, and interfacial tension  
51  
52 exhibited by the supercritical CO<sub>2</sub>-brine system [6-8]. The variability of fluid properties  
53

1  
2  
3  
4 complicates predictions of flow patterns and displacement mechanisms. Further, it has been  
5  
6 shown that the initial (post-drainage) state of the reservoir has a substantial impact on the amount  
7  
8 of residual capillary trapped NW phase present in the system after imbibition [9, 10]. However,  
9  
10 experimental work with supercritical fluids is a non-trivial exercise, necessitating methods to  
11  
12 approximate supercritical conditions with ambient experiments; Herring et al. [11] demonstrated  
13  
14 that ambient condition micromodels were able to accurately predict the flow regime for a  
15  
16 supercritical CO<sub>2</sub> drainage process in sandstone cores through application of a dimensional  
17  
18 analysis.  
19  
20  
21  
22

23  
24 We explore capillary trapping of NW phase from two perspectives. First, we investigate  
25  
26 how consideration of the dominant forces at play via the *pore-scale force balance* in a system  
27  
28 allows for comparison and better understanding of results from a wide range of experiments. The  
29  
30 second study area results from the unique ability to engineer the drainage (CO<sub>2</sub> injection)  
31  
32 process, and thus the initial (i.e. post-drainage) state. To this end, we use three dimensional (3D)  
33  
34 metrics which can be used to describe NW fluid topology (connectivity) within porous media. In  
35  
36 particular, we develop the relationship between initial NW fluid connectivity and the residual  
37  
38 state of a system which was first investigated by Herring et al. [10], with new analysis of a high  
39  
40 quality data set collected via x-ray computed microtomography (x-ray CMT) experiments  
41  
42 performed at the Advanced Photon Source at Argonne National Laboratory. Finally, we provide  
43  
44 physical interpretation of these relationships.  
45  
46  
47  
48  
49

50  
51 Consideration of pore scale forces and fluid topology allow drainage and imbibition  
52  
53 processes to be efficiently engineered to provide favorable residual conditions. Geologic CO<sub>2</sub>  
54  
55 sequestration scenarios are used as an example to illustrate these concepts.

## 2.0 Background

### 2.1 Pore scale forces

Considerable previous research has been conducted on the topic of residual (i.e. capillary trapped) NW saturation in porous media, with many different W and NW fluids, and in different media. To facilitate characterization of fluid flow over a range of properties, the experiments discussed in this work are characterized by the dimensionless ratios of capillary number (Ca) and Bond number (Bo).

Ca has been presented in several different forms, and has traditionally been defined from an oil extraction standpoint [12-14]. In general, Ca describes the balance between viscous forces and capillary forces with respect to the invading fluid (as opposed to the defending fluid). In this work, Ca is defined as:

$$Ca = \frac{\text{Viscous Force}}{\text{Capillary Force}} = \frac{\mu_{INV} v_{INV}}{\sigma} = \frac{\mu_{INV} \frac{Q_{INV}}{A \cdot \eta}}{\sigma} \quad (\text{eqn. 1})$$

where  $\mu_{INV}$  is the invading phase viscosity [mPa·s],  $v_{INV}$  is the invading phase Darcy velocity [m/s], and  $\sigma$  is the interfacial tension [mN/m] between the invading and defending fluid. The invading phase velocity is computed as the volumetric flow rate  $Q$  [m<sup>3</sup>/s] divided by the cross-sectional area  $A$  [m<sup>2</sup>] of the porous medium and the porosity  $\eta$  [-]. Note that while Ca is defined as a function of the invading fluid, and is thus dependent upon whether the system is undergoing imbibition (brine is the invading phase) or drainage (CO<sub>2</sub> is the invading phase).

Previous work has shown that under certain conditions, the Ca of the imbibition process determines the trapped NW saturation of the post-imbibition, residual state [12, 15, 16]. When a relationship between imbibition Ca and residual NW saturation is apparent, it is described by a constant residual saturation value for low imbibition Ca values with a sharp decrease in residual

1  
2  
3  
4 saturation as Ca of the imbibition process increases above the threshold or “critical” capillary  
5  
6 number [14, 15]; this is shown in Figure 1 (modified from Cense and Berg [14]).  
7  
8

9 This relationship between Ca and NW saturation post-imbibition has been shown during  
10  
11 NW desaturation experiments wherein the initial-state system (NW fluid is present in the  
12  
13 medium) is water-flooded at increasing flow rates and the NW phase saturation in the core is  
14  
15 measured as a function of Ca [14-17]; it is shown in sets of drainage-imbibition experiments  
16  
17 conducted at different imbibition Ca [10, 16] and has also been supported by modeling results  
18  
19 [18, 19]. However, Ca is not a complete descriptor of trapping in a porous medium, because the  
20  
21 curves describing the dependence of residual saturation on Ca can shift due to changes in NW  
22  
23 fluid properties [20] or medium properties [19]. Additionally, other experimental studies in  
24  
25 different systems have found reduced or no dependence on Ca [21-23].  
26  
27  
28  
29  
30

31 In a 3D system, the gravity force is considered via the Bond number (Bo); which here is  
32  
33 defined as:  
34  
35

$$36 \quad Bo = \frac{\text{Gravity Force}}{\text{Capillary Force}} = \frac{\Delta\rho \cdot g \cdot d^2}{\sigma} \quad (\text{eqn. 2})$$

37  
38  
39 where  $\Delta\rho$  is the density difference between the two fluids [ $\text{kg/m}^3$ ],  $g$  is the acceleration of  
40  
41 gravity [ $\text{m/s}^2$ ], and  $d$  is the representative length scale [m]. Here, in order to emphasize that  
42  
43 forces are examined from a *pore-scale* perspective, as well as for ease of comparison with other  
44  
45 studies,  $d$  is defined as the median grain diameter (or equivalent grain diameter for a  
46  
47 micromodel); this is in agreement with Mohammadian et al. [24]. Note that while Ca is defined  
48  
49 as a function of the invading fluid, and is thus dependent upon whether the system is undergoing  
50  
51 imbibition or drainage, Bo is constant for a given fluid pair-porous medium system.  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 A combination of these two dimensionless numbers presents a description of the ratio of  
5  
6  
7 viscous to gravity forces:

$$8 \quad Ca \cdot Bo^{-1} = \frac{\text{Viscosity}}{\text{Capillarity}} \frac{\text{Capillarity}}{\text{Gravity}} = \frac{\text{Viscous Force}}{\text{Gravity Force}} = \frac{\mu_{INV} v_{INV}}{\Delta \rho \cdot g \cdot d^2} \quad (\text{eqn. 3})$$

9  
10  
11 Following Polak et. al., [25] we will use a combination of the dimensionless numbers Ca and Bo  
12  
13 to determine which forces are dominant during the imbibition process, on a pore-scale basis, in a  
14  
15 3D porous medium system. Figure 2 shows the location of a number of existing 3D multiphase  
16  
17 flow studies overlaid onto the pore scale force balance diagram. As suggested by Polak et al.  
18  
19 [25], we suggest that the relative location of a system within the pore-scale force balance  
20  
21 illustrates which force(s) has the greatest impact on flow processes. In their study, Polak and  
22  
23 colleagues demonstrated the interplay of all three forces (capillary, viscous, and gravity)  
24  
25 resulting in a figure very similar to that shown in Figure 2; however, we have modified their  
26  
27 original formulation via reformulation of the representative length scale  $d$  in Bo in order to more  
28  
29 easily accommodate comparison of a wider range of experimental studies and to emphasize that  
30  
31 we examine these systems on a pore-scale basis.  
32  
33  
34  
35  
36  
37  
38

39 We note here that the Ca values presented in this work are derived from the traditional  
40  
41 macroscopic formulation, in contrast with recent works which define Ca from a pore-scale  
42  
43 perspective wherein properties of individual NW phase clusters are considered and incorporated  
44  
45 into the Ca formulation [26, 27]. The pore-scale formulations [26, 27] more accurately describe  
46  
47 the physics of mobilization of NW fluid on a pore-scale basis, but also require highly detailed  
48  
49 and complete pore-scale descriptions of NW phase to adequately calculate Ca values. In our non-  
50  
51 dimensional analysis, we utilize the traditional Ca as defined in equation 1 in order to facilitate  
52  
53 inclusion of several previous studies for which detailed measures of individual NW fluid clusters  
54  
55 are unavailable. Also note that media are assumed to be strongly wetting systems, as contact  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 angle is not incorporated into the dimensionless numbers presented in equations 1-3. Finally,  
5  
6 medium topology and morphology (coordination number, pore-throat aspect ratio) and other  
7  
8 media features (e.g. porosity, consolidated vs. unconsolidated) which may also be important to  
9  
10 multiphase fluid flow are not well-represented by this model; nor is the defending fluid viscosity.  
11  
12 As a consequence of these limitations, this analysis should be considered to be an “order of  
13  
14 magnitude” approximation.  
15  
16  
17

18  
19 The studies presented in Figure 2 lie within several general areas of force dominance. For  
20  
21 studies with systems which lie in the upper right corner of the figure, both capillary and viscous  
22  
23 forces are important; in this regime there is a transition between whether capillary and viscous  
24  
25 forces dominate, and trends of residual saturation with  $Ca$  are evident; e.g. Chatzis et al. [16]  
26  
27 found that residual saturation and NW blob morphology after imbibition was a function of  $Ca$ .  
28  
29 However, in this area of the figure, gravity forces play a minor role, explaining the findings of  
30  
31 Mayer and Miller [28] and Gittins et al. [29] which state that the bead/grain size (equivalent to  $d$ ,  
32  
33 a gravity force parameter) has no effect on the amount residual NW saturation. For experimental  
34  
35 systems closer to the bottom left of the figure, gravity forces impact the experiments, e.g. the  
36  
37 experiments of Morrow et al. [15] range from the capillary-viscosity dominated regime to the  
38  
39 gravity dominated regime, and the results of that study demonstrate a significant dependence on  
40  
41 both  $Ca$  and  $Bo$ . Moving down Figure 2 (further away from the capillary dominated regime and  
42  
43 into gravity dominated space), the experiments of Mayer and Miller [21] showed that blob  
44  
45 morphology exhibited a strong dependence on  $Bo$ , and only a very weak dependence on  $Ca$ .  
46  
47 More recently, Harper et al. [22] found no correlation of residual NW saturation with  $Ca$ , but  
48  
49 rather that  $Bo$  and defending phase viscosity were the most significant parameters. Similarly,  
50  
51 Geistlinger et al. [23] found no correlation of residual saturation with  $Ca$ , and rather that trapped  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 NW phase is dependent on pore size distribution (again, a parameter which indicates gravity  
5  
6 dependence).

7  
8  
9 This non-dimensional analysis explains the differences in findings of experimental  
10 studies with a large range of porous media, flow conditions, and fluid pairs; and resolves some of  
11 the seeming contradictions that have been observed by experimentalists. The location in the force  
12 dominance plot of the brine-air-Bentheimer sandstone experiments of this study are shown with  
13  
14 the approximate location of supercritical CO<sub>2</sub> sequestration scenarios, given the range of  
15  
16 supercritical CO<sub>2</sub> fluid properties attainable and assuming similar media to Bentheimer  
17  
18 sandstone (Figure 2). In light of the above discussion, we expect capillary and viscous forces to  
19  
20 dominate both the brine-air-Bentheimer ambient condition experimental system as well as a  
21  
22 geologic supercritical CO<sub>2</sub> sequestration scenario.  
23  
24  
25  
26  
27  
28  
29  
30

## 31 32 **2.2 Initial State Topology**

33 Following Herring et al. [10], we refer to a system uniformly saturated with W fluid to be  
34 in the *original* state; a post-drainage system (i.e. NW is introduced to the system) as being in the  
35  
36 *initial* state; and a post-imbibition system as the *residual* state. The well-documented capillary  
37  
38 pressure hysteresis present in multiphase systems (e.g. Morrow, 1970 [30]) dictates that the  
39  
40 residual state (and thus, trapped NW saturation) is dependent on the initial state. The relationship  
41  
42 between initial and residual NW saturation ( $S_I$  and  $S_R$ , respectively) in porous media has been  
43  
44 investigated and described empirically by the so-called Land's model; it has been established  
45  
46 that as initial NW saturation increases, residual NW saturation increases towards a plateau-like  
47  
48 maximum [2, 31]. An alternate means to visualize this relationship is to examine the “trapping  
49  
50 efficiency” (i.e.  $S_R/S_I$ ) as a function of initial NW saturation:  $S_R/S_I$  is highest at relatively low  $S_I$   
51  
52 values, and decreases as  $S_I$  continues to increase [3]. While these empirical relationships are well  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 characterized for a variety of porous media systems, the underlying physical mechanisms for this  
5  
6 behavior remain relatively poorly understood. As originally suggested by Wardlaw and Yu [32],  
7  
8 and further examined by Herring et. al. [10], we propose that the reason for the plateau in the  
9  
10 Land’s model description of trapping and the associated decrease in trapping efficiency at high  $S_I$   
11  
12 values is due to high connectivity of the NW phase at high NW saturation: as the NW fluid  
13  
14 becomes highly interconnected via increasing numbers of pore throats, the pathways available  
15  
16 for mobilization dramatically increase.  
17  
18  
19  
20

21 We have previously investigated this phenomenon by examining trapping efficiency as a  
22  
23 function of initial NW phase topology, specifically, as quantified by the initial normalized NW  
24  
25 Euler number ( $\hat{\chi}$ ) [10]. Herein, we further develop and compare this approach to another  
26  
27 quantitative descriptor of connectivity, the gamma function ( $\Gamma$ ), which is a statistical percolation  
28  
29 metric described by Renard and Allard [33].  
30  
31  
32  
33

### 34 **2.2.1 Topological Invariants**

35 Topological invariants are properties of objects which are not changed by continuous  
36  
37 deformations such as stretching, bending, and twisting; they are only changed when parts of an  
38  
39 object are discontinuously deformed (i.e. “torn” or “glued together”). Topological invariants  
40  
41 describe an object’s connectivity; in comparison to an object’s geometry, which describes its  
42  
43 shape. The Euler number ( $\chi$ ) is a topological invariant defined as the alternating sum of the first  
44  
45 three Betti numbers ( $\beta_0, \beta_1, \beta_2$ ):  
46  
47  
48  
49

$$50 \chi = \beta_0 - \beta_1 + \beta_2 \quad (\text{eqn. 5})$$

51 where  $\beta_0$  is the number of individual objects present,  $\beta_1$  is the number of redundant loops or  
52  
53 handles present (e.g. the handle on a coffee mug or the loop of a doughnut), and  $\beta_2$  is the number  
54  
55 of holes or hollows within the object(s) present. Previous studies have utilized Euler values to  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 characterize connectivity of sintered copper porous cores [34] and bone tissue [35]. Applied to a  
5  
6 fluid phase within a porous medium,  $\beta_0$  can be thought of as the number of distinct, individual  
7  
8 fluid clusters;  $\beta_1$  is the number of redundant connections via pore throats within the clusters; and  
9  
10  $\beta_2$  is the number of bubbles of a different fluid or solid particles suspended in the fluid. For this  
11  
12 work, we investigate the topology of a less-dense NW fluid (air), which implies that  $\beta_2$  will be  
13  
14 zero (i.e. no “floating” water droplets or rock grains in the air phase). Thus  $\beta_2=0$  for conversion  
15  
16 between Euler number and Betti numbers; this is in agreement with analysis by Vogel [36]. A  
17  
18 topological description of the connectivity of a fluid phase in a porous medium is fairly intuitive;  
19  
20 during a drainage process, for example, as fluid clusters coalesce and grow together, the number  
21  
22 of individual objects ( $\beta_0$ ) decreases; and as more and smaller pore throats are invaded, the  
23  
24 number of redundant connections within the fluid clusters ( $\beta_1$ ) increases. This leads to an overall  
25  
26 decrease in Euler number; therefore, as Euler number becomes more and more negative, the NW  
27  
28 phase fluid is becoming better connected. At some critical value of NW saturation, the NW  
29  
30 phase will be connected across the domain; the transition from dominantly disconnected ( $\chi > 0$ )  
31  
32 to dominantly connected ( $\chi < 0$ ) is related to the percolation threshold for a given phase [36, 37]  
33  
34 and the saturation at which the Euler number is exactly zero is an estimate of the saturation  
35  
36 percolation threshold for NW phase flow.  
37  
38  
39  
40  
41  
42  
43  
44

45  
46 The Euler number is an *extensive* property of a system in that the overall Euler number  
47  
48 for a domain is the sum of the values of all subdomains within it. Therefore the Euler number  
49  
50 depends on the scale over which it is measured; the Betti numbers are also scale-dependent.  
51  
52 Values of the Euler number or Betti numbers calculated on one section of an object are *local*  
53  
54 (rather than *global*) values, and are therefore not representative of the total overall object, nor are  
55  
56 they necessarily representative of other same-sized subsections of the object due to statistical  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 variation or small-scale heterogeneities. However, appropriate normalization of the Euler or Betti  
5  
6 values leads to a more representative metric. Herring et al. [10] calculated Euler numbers for the  
7  
8 entire pore space (i.e. Euler numbers for systems at 100% NW phase saturation), and normalized  
9  
10 the Euler number for the system at a given saturation by the Euler number at 100% NW phase  
11  
12 saturation:  
13  
14

$$\hat{\chi}_{NW} = \chi_{NW} / \chi_{100\%NW} \quad (\text{eqn. 6})$$

15  
16  
17  
18 This normalization results in a connectivity metric with a maximum value (most connected) of  
19  
20 1.0, where negative values indicate disconnectedness. A representative elementary volume  
21  
22 (REV) analysis (see supplementary materials, available online) demonstrates that  $\hat{\chi}_{NW}$  can be  
23  
24 used as a representative measure of NW phase connectivity for a given sample. However, values  
25  
26 of  $\hat{\chi}_{NW}$  are highly dependent on the value of  $\chi_{100\%NW}$ , so accurate measurement of this  
27  
28 parameter is essential.  
29  
30  
31  
32

### 33 **2.2.2 Statistical Percolation Metrics**

34  
35  
36 The term “percolation” refers to the transition from individual, disconnected clusters to  
37  
38 one large cluster which spans the length of the porous domain; e.g. once a single NW phase  
39  
40 pathway is established all the way through a porous medium, the NW fluid can be said to  
41  
42 percolate through the media.  $\Gamma$  is a probability-based percolation metric described by Renard and  
43  
44 Allard [33] and is defined here as a function of permeable phase saturation,  $p$ . In the context of  
45  
46 NW phase fluid transport, we define the permeable phase  $p$  to be NW fluid:  $\Gamma(\text{NW})$  is the ratio of  
47  
48 the sum of squares of all individual NW phase cluster volumes to the square of the total NW  
49  
50 phase volume present in the domain. From an image analysis perspective,  $\Gamma(\text{NW})$  can be  
51  
52 approximated by calculating the ratio of pairs of individual NW voxels that are connected to all  
53  
54 the possible pairs of NW voxels, and can be computed directly from the cluster size distribution:  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

$$\Gamma(\text{NW}) = \frac{1}{n_{\text{NW}}^2} \sum_{i=1}^{N(\text{X}_{\text{NW}})} n_i^2 \quad (\text{eqn. 7})$$

where  $n_{\text{NW}}$  is the total number of NW phase voxels in the set  $\text{X}_{\text{NW}}$ ,  $N(\text{X}_{\text{NW}})$  is the number of distinct clusters in the set  $\text{X}_{\text{NW}}$ , and  $n_i$  is the number of NW voxels in cluster  $i$ .

As  $\Gamma(\text{NW})$  approaches 1.0, the fraction of the fluid that lies in a single cluster increases. In contrast to the *local* Euler values described above, this metric is *global*: whereas Euler number values can be measured on individual objects within the domain and subsequently summed to find the overall Euler number value for the entire domain,  $\Gamma(\text{NW})$  must be computed over the entire domain of the system by necessity. By value of being a probability metric,  $\Gamma(\text{NW})$  can be assumed to be representative of a given sample without further manipulation or normalization (again assuming a representative elementary volume has been achieved, see the supplemental materials (available online) for REV analysis of  $\Gamma(\text{NW})$ ). Also note that the definition of  $\Gamma$  inherently weights clusters by their size, unlike the Euler number; with the result that  $\Gamma(\text{NW})$  is much less susceptible to noise which would manifest as falsely labeled NW voxels.

### 3.0 Materials and Methods

The complete experimental set-up and process is similar to that of Herring et al. [10] and only deviations from the previous study and the general process will be described here.

Experiments were conducted with two 6.2 mm diameter Bentheimer sandstone cores of lengths of approximately 21 mm. Air was the NW fluid, and the W fluid was brine made of degassed millipore DI water doped with potassium iodide (KI), one part KI to six parts water by weight. The core was first vacuum-saturated with brine, and an x-ray tomographic scan was taken to characterize the original NW phase saturation ( $S_0$ ) inside the core. Then brine was drained from the bottom of the core (as ambient air was passively pulled into the top of the core) at a flow rate of 0.2 ml/hr via a Harvard PHD2000 syringe pump (Harvard Apparatus, Holliston MA, United

1  
2  
3  
4 States) to a preselected initial NW phase saturation ( $S_I$ ) value ( $S_I$  values ranged from 42%-93%).  
5  
6 The system was allowed to equilibrate until capillary pressure readings stabilized, and another  
7  
8 tomographic scan was collected. Finally, brine was imbibed into the bottom of the core at one of  
9  
10 three different flow rates (0.018 ml/hr, 1.8 ml/hr, or 54 ml/hr) as air was flushed out the top of  
11  
12 the core, and a scan was acquired of the residual NW phase saturation ( $S_R$ ). For three  
13  
14 experiments, the core was dried under vacuum resulting in relatively high NW saturation (e.g.  
15  
16 94%-100% NW saturation), and the imbibition process was performed on the “dry” core. A  
17  
18 pressure transducer (Validyne Engineering, Northridge CA, United States) with a range of 14.0  
19  
20 kPa was connected in parallel with the brine flow line to measure capillary pressure response.  
21  
22  
23

24  
25  
26 Tomographic imaging was performed at the bending magnet beam-line at sector 13  
27  
28 (GSECARS) at the Advanced Photon Source at Argonne National Laboratory; specifications for  
29  
30 the beamline have previously been reported [38-40]. Scans were performed at a monochromatic  
31  
32 energy level of 33.269 keV, just above the K-shell photoelectric absorption edge of iodine  
33  
34 (33.169 keV), resulting in x-ray attenuation by the KI-doped brine and thus allowing for  
35  
36 separation of the W and NW fluids in the reconstructed images. Images were captured at 720  
37  
38 angles, with a voxel resolution of 5.8  $\mu\text{m}$ .  
39  
40  
41

42  
43 After reconstruction, a cylindrical subsection of diameter 975 voxels and height 600  
44  
45 voxels (approximately 90  $\text{mm}^3$ ) was chosen which excludes the walls from the volumes (Figure  
46  
47 3a). This data size is larger than the determined REV for connectivity measures of 600 x 600 x  
48  
49 600 voxels, which is equivalent to a physical volume of 40  $\text{mm}^3$  (see supplemental materials  
50  
51 online). A median filter was applied to smooth the images and reduce random noise (Figure 3b),  
52  
53 and a histogram of the grayscale values present in each volume was calculated. The histogram  
54  
55 minimum separating those grayscale values representing air and those representing sandstone  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 grains or brine were determined for each volume (Figure 3d), and the threshold value was set  
5  
6 equivalent to this minimum value resulting in the final binarized data volume (Figure 3c).  
7  
8 Finally, a size exclusion filter was applied which removed air-labeled clusters less than 125  
9  
10 voxels; this volume corresponds to a spherical pore of radius 18  $\mu\text{m}$  which is below the  
11  
12 minimum pore size of Bentheimer (pore size distribution measured by Maloney et al. [41]). This  
13  
14 process results in a binary image with only NW phase labeled. Avizo Fire<sup>TM</sup> was then used to  
15  
16 quantify NW saturation, cluster volumes, cluster numbers, and Euler numbers. The numerical  
17  
18 methods utilized in Avizo Fire<sup>TM</sup> for quantification of Euler number values are detailed by  
19  
20 Odgaard and Gundersen [35]; 26-neighborhood voxel connectivity is utilized for these  
21  
22 calculations. All saturation values presented in the results are calculated from x-ray CMT images  
23  
24 as opposed to the measured pumped by the syringe pump, as the accuracy of pumped volumes  
25  
26 can suffer from dead volume and bubble effects.  
27

32  
33  
34  
35

#### 36 **4.0 Sensitivity of Connectivity Metrics to Image Quality**

37 Because of their dependence on very small features, image-derived connectivity metrics  
38  
39 may be sensitive to various image quality parameters, for example: noise levels, data resolution,  
40  
41 the type of filters applied to the data, segmentation method, and segmentation threshold values.  
42  
43 Additionally, in order to provide an accurate representation of the connectivity of the system,  
44  
45 quantitative connectivity metrics must be calculated on an REV. An investigation into the  
46  
47 sensitivity to these factors of both the normalized Euler value ( $\hat{\chi}$ ) and  $\Gamma(\text{NW})$  was conducted and  
48  
49 is presented in the supplemental materials available online; for brevity, only the results are  
50  
51 highlighted here. In order to examine the sensitivity of these parameters on a wider range of  
52  
53 image-based data, the relatively high quality data (with respect to phase contrast, noise, and  
54  
55 voxel resolution) presented in this study which was collected at the Advanced Photon Source at  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Argonne National Lab at a resolution of 5.8  $\mu\text{m}$  (denoted “APS” data) was compared to data  
5  
6 presented in Herring et.al. [10] which was collected via a polychromatic bench-top x-ray CMT  
7  
8 system at Oregon State University at a resolution of approximately 10  $\mu\text{m}$  (denoted “OSU” data).  
9  
10  
11 Image parameters for both data sets are shown in Table A.1 in the supplementary materials.  
12

13  
14 Based on the analysis of the two data sets, we established the following conclusions  
15  
16 regarding the significance of these image quality parameters on the calculation of  $\hat{\chi}_{NW}$  or  
17  
18  $\Gamma(\text{NW})$ :  
19

- 20  
21 • Noise which manifests as small, isolated, falsely labeled NW voxels has no  
22  
23 significant impact on  $\Gamma(\text{NW})$ ; and no significant impact on  $\hat{\chi}_{NW}$  as long as a  
24  
25 minimum level of noise removal is applied. In the case of the high resolution APS  
26  
27 data, noise reduction was achieved using a median filter on the grayscale image  
28  
29 and by processing the segmented (binary) data to remove isolated NW clusters  
30  
31 smaller than 52 voxels (equivalent to a sphere with a radius of 13  $\mu\text{m}$ ) was  
32  
33 sufficient to provide consistent  $\hat{\chi}_{NW}$  calculations.  
34  
35
- 36  
37 • A representative elementary volume (REV) for the APS data is achieved at  
38  
39 approximately  $600 \times 600 \times 600$  voxels (equivalent to a cube of  $42.14 \text{ mm}^3$ , or  
40  
41 3.48 mm per side) for both  $\hat{\chi}_{NW}$  and  $\Gamma(\text{NW})$  in Bentheimer sandstone. Use of an  
42  
43 analytical volume smaller than the REV has a relatively small effect on the  
44  
45 calculation of  $\hat{\chi}_{NW}$ , and a dramatic effect on the calculation of  $\Gamma(\text{NW})$  .  
46  
47
- 48  
49 • Image resolution has minimal impact on calculation of both  $\hat{\chi}_{NW}$  and  $\Gamma(\text{NW})$  for  
50  
51 the range of resolution investigated (5.8  $\mu\text{m}$  and 10  $\mu\text{m}$ ).  
52  
53
- 54  
55 • Data processing schemes (i.e. filters and threshold detection method applied) have  
56  
57 a significant effect on both  $\hat{\chi}_{NW}$  and  $\Gamma(\text{NW})$ . The OSU data presented in Herring  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 et al. [10] was originally processed using ROCK3DMA, an Indicator Kriging  
5  
6 segmentation algorithm [42]. Comparison of the original OSU Indicator Kriging  
7  
8 results with the APS data (which was smoothed using a median filter, denoised,  
9  
10 and segmented via simple grayscale histogram thresholding as described in  
11  
12 Section 3) demonstrates disagreement in the  $\hat{\chi}_{NW}$ -saturation and  $\Gamma(NW)$ -  
13  
14 saturation relationships and in absolute  $\hat{\chi}_{NW}$  and  $\Gamma(NW)$  values. Reprocessing the  
15  
16 grayscale OSU data by the same process as the APS data resolves this  
17  
18 disagreement in the calculation of  $\hat{\chi}_{NW}$ , but  $\Gamma(NW)$  remains inconsistent between  
19  
20 the data sets. This highlights that different data sets must be processed and evaluated  
21  
22 carefully to ensure accurate comparison.  
23  
24  
25  
26  
27

- 28 • For data with unfavorable grayscale histograms due to the lack of distinctive  
29  
30 peaks or poorly defined minima between the NW and solid/W phases, the choice  
31  
32 of grayscale segmentation threshold has a minor effect on the calculation of  
33  
34  $\Gamma(NW)$ , but a significant effect on the calculation of  $\hat{\chi}_{NW}$ . For these grayscale  
35  
36 images (16 bit precision), changing the threshold by  $\pm 100$  grayscale values results  
37  
38 in approximately a  $\pm 20\%$  shift in  $\hat{\chi}_{NW}$  (Table A.2). For images with poorly  
39  
40 defined histogram peaks, a consistent and objective threshold detection system is  
41  
42 therefore necessary.  
43  
44  
45  
46  
47

48 It is important to note that for the image quality parameters which are highly important to  
49  
50 connectivity metric calculations (i.e. data processing procedure and threshold determination) the  
51  
52 most significant impacts are imparted on the images with the most NW fluid present: the dry, or  
53  
54 100% NW fluid filled, scan of the porous medium. As indicated by Equation 6 and noted above,  
55  
56 the determination of  $\chi_{100\%NW}$  has a large impact on the analysis of the entire data set. Accurate  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 acquisition, processing, and analysis of the dry scan of the medium is of great importance in  
5  
6 ensuring the relevance and applicability of the overall data analysis.  
7  
8

9 As described in Section 3.0, for the relatively high quality experimental data of this  
10 study, all quantitative metrics are calculated on a data set larger than the required REV, and a  
11 median filter was utilized for noise removal and smoothing. The resulting histogram of measured  
12 grayscale values exhibited very well defined peaks (Figure 3d), allowing for accurate separation  
13  
14 of NW and combined W/solid phases. Minimal post-segmentation noise removal (removal of  
15  
16 isolated NW labeled clusters smaller than 125 voxels) was used. Based on the presented  
17  
18 sensitivity analysis, we are confident that this procedure results in reliable quantitative values.  
19

## 28 **5.0 Results**

### 29 **5.1 Force Balance Analysis and Traditional Empirical Relationships**

30  
31 Traditionally, capillary trapping has been investigated by examining the various  
32 relationships between initial NW saturation ( $S_I$ ), residual NW saturation ( $S_R$ ), and imbibition  
33 capillary number ( $Ca$ ); for example see Chatzis and Morrow [12], Chatzis et al. [16], Al  
34 Mansoori et al. [2], and Land [31]. Both capillary trapping efficiency ( $S_R/S_I$ ) and total capillary  
35 trapping ( $S_R$ ) are important parameters to CO<sub>2</sub> sequestration operations, and can be investigated  
36 as a function of  $S_I$  and imbibition  $Ca$  (Figure 4). The Bentheimer sandstone cores used in this  
37 study are relatively uniform and we expect a high level of consistency between experiments  
38 performed in different cores; thus, data presented in Figure 4 and subsequent figures include a  
39 combination of the results of both cores.  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54

55 From the force balance analysis presented in Section 2.1, our Bentheimer-brine-air  
56 system is expected to be dominated by capillary and viscous forces; as is a supercritical CO<sub>2</sub>-  
57 brine-sandstone system (given the range of supercritical CO<sub>2</sub> fluid properties attainable and  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 assuming similar media to Bentheimer sandstone; red trapezoid in Figure 2). Thus, the residual  
5  
6 state of both systems should depend on imbibition  $Ca$ . Bond number ( $Bo$ ) values for the  $CO_2$ -  
7  
8 brine-sandstone system are approximately an order of magnitude smaller than those for the  
9  
10 Bentheimer-brine-air system (i.e. the  $CO_2$ -brine-sandstone system has less gravity force  
11  
12 influence than the ambient condition experimental system, due to the relative similarity in  $CO_2$   
13  
14 and brine densities as compared to the density difference of air and brine). However, neither  
15  
16 system exists in a gravity dominated regime, so we expect that the ambient Bentheimer-brine-air  
17  
18 system will produce results that are similar to a geologic  $CO_2$  sequestration operation.  
19  
20  
21  
22  
23

24  
25 As shown, the expected trends of decreased total NW capillary trapping ( $S_R$ ) and  
26  
27 decreased trapping efficiency ( $S_R/S_I$ ) with increasing imbibition  $Ca$  are present (Figure 4a and  
28  
29 4b), as is the traditional Land's model description of increasing residual NW saturation with  
30  
31 increasing initial NW saturation (Figure 4c). However, there is a large amount of scatter in the  
32  
33 data which is not resolved by normalizing the residual saturation by the initial saturation, or by  
34  
35 grouping the data by the imbibition  $Ca$  value; this discrepancy is investigated in the next section.  
36  
37  
38  
39

## 40 **5.2 Inclusion of Connectivity**

41  
42 In order to understand the variability inherent in these results as described by the  
43  
44 empirical models above, we consider how the connectivity of the NW phase impacts trapping  
45  
46 results. First, though, we investigate how the connectivity characteristics of the normalized Euler  
47  
48 characteristic ( $\hat{\chi}$ ) and  $\Gamma(NW)$  manifest for NW fluid within porous media during the drainage  
49  
50 process via the relationship between each connectivity metric and initial NW saturation (Figure  
51  
52 5).  
53  
54  
55  
56

57  
58 Here the differences in these connectivity metrics are dramatically apparent.  $\Gamma(NW)$   
59  
60 approaches a value of unity at relatively low saturation, implying that the majority of the NW  
61  
62  
63  
64  
65

1  
2  
3  
4 phase present is connected to the main cluster by at least one pore throat throughout the drainage  
5  
6 process, with increasing probability that any isolated NW cluster will become connected to the  
7  
8 main cluster as initial NW saturation increases. Above an initial NW saturation of approximately  
9  
10 80%, the variation in  $\Gamma(\text{NW})$  is negligible; implying that at NW saturation at or above 80%, all  
11  
12 NW phase is connected via at least one pore throat within the medium.  
13  
14  
15

16  
17 The  $\hat{\chi}$  value provides a fundamentally different quantitative description of the NW fluid  
18  
19 connectivity. At initial NW saturation greater than 50%, the number of NW clusters ( $\beta_0$ ) roughly  
20  
21 matches the number of connections within individual clusters ( $\beta_1$ ), as indicated by  $\hat{\chi}_{\text{NW}} \approx 0$ . In  
22  
23 direct comparison to  $\Gamma(\text{NW})$ ,  $\hat{\chi}$  shows the most dramatic growth at values greater than 80% NW  
24  
25 saturation, i.e. long after the largest cluster has already formed as evaluated by  $\Gamma(\text{NW})$ .  $\Gamma(\text{NW})$   
26  
27 values show that above 80%, almost all NW fluid is already connected and distinct individual  
28  
29 fluid clusters are minimized, thus, the increase in  $\hat{\chi}$  is due to the increase in redundant  
30  
31 connections,  $\beta_1$ . Consideration of  $\Gamma(\text{NW})$  and  $\hat{\chi}_{\text{NW}}$  together demonstrates both the degree and  
32  
33 manner of NW phase connectivity within the porous medium: for the post-drainage Bentheimer-  
34  
35 air-brine system, the NW phase is largely connected via one large cluster; and as NW saturation  
36  
37 increases, the NW phase invades additional pore throats *within* this single cluster.  
38  
39  
40  
41  
42  
43  
44

45 This interpretation is further demonstrated by the approximately linear relationship  
46  
47 between  $\hat{\chi}$  and the equilibrium capillary pressure (the difference in pressure between the NW  
48  
49 phase and the W phase) at the end of the drainage process (Figure 6). As capillary pressure  
50  
51 increases, more (and smaller) pore throats are invaded, and  $\hat{\chi}_{\text{NW}}$  increases.  
52  
53  
54  
55

56 A  $\hat{\chi}$  value of zero provides an estimate of the percolation threshold; i.e. the NW  
57  
58 saturation value at which NW phase fluid is connected throughout the porous medium, spanning  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 the entirety of the domain [36, 37]. The relationship between initial  $\hat{\chi}_{NW}$  and NW saturation  
5 demonstrated by the experimental data (Figure 5) shows that  $\hat{\chi}_{NW} = 0$  at NW saturation of  
6 approximately 50% within Bentheimer sandstone. A computational approach for predicting  
7 pressure-saturation curves in media was described by Hazlet [43] and further by Hilpert and  
8 Miller [44] wherein morphological opening with a sphere of incrementally increasing radius is  
9 performed on a binary representation of a porous medium (i.e. the dry image of the medium),  
10 and saturation and pressure values are calculated by simulation at each opening step. A similar  
11 process was applied here, wherein the opening procedure was performed on binary volumes of  
12 dry Bentheimer sandstone using Avizo Fire<sup>TM</sup>. After each opening step, isolated NW fluid  
13 clusters (<10,000 voxels or a sphere of radius 77.5  $\mu\text{m}$ ) resulting from the opening process which  
14 were not connected to the main fluid clusters were removed.  $\hat{\chi}_{NW}$  and saturation values were  
15 calculated for each successive opening; the results of this analysis are compared with the  
16 experimental data (Figure 7). The morphological opening procedure conducted on the dry  
17 images resembles the  $\hat{\chi}_{NW}$  values at initial saturation to within a reasonable approximation,  
18 demonstrates that  $\hat{\chi}_{NW} = 0$  at NW phase saturation of 50% (providing additional evidence that  
19 the NW phase percolation threshold for Bentheimer sandstone is at a NW saturation of  
20 approximately 50%), and suggests that the  $\hat{\chi}_{NW}$ -saturation relationship for a given medium  
21 might be approximated from one high-quality (i.e. adequate resolution and low noise level) scan  
22 of a dry porous media rather than from multiple time-consuming experimental drainage  
23 observations.

52  
53  
54 Following Herring et al. [10], we investigate the impact of connectivity on capillary  
55 trapping efficiency (Figure 8); these data are classified by the imbibition process Ca as in Figure  
56  
57  
58  
59 4c. While both  $\Gamma(NW)$  and  $\hat{\chi}_{NW}$  plots show a relationship between capillary trapping efficiency  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 and connectivity, the relationship between normalized initial  $\hat{\chi}_{NW}$  and trapping efficiency shows  
5  
6 a strong linear correlation (Figure 8a), compared to  $\Gamma(NW)$  (Figure 8b) where the trend is non-  
7  
8 linear due to insensitivity of  $\Gamma(NW)$  in the high NW saturation range. This suggests that while  
9  
10 NW trapping is certainly related to the general connectivity of the NW phase, the capillary  
11  
12 trapping/mobilization process is directly related to the NW topology as described by the Euler  
13  
14 characteristic. An increase in the number of redundant pore throats ( $\beta_1$ ) which connect NW fluid  
15  
16 *within* the fluid clusters, that is, a higher initial  $\hat{\chi}_{NW}$  value, is equivalent to a higher number of  
17  
18 potential pathways through which NW fluid can be mobilized, and results in decreased trapping  
19  
20 efficiency. Note also that the high and intermediate imbibition Ca data show a relatively strong  
21  
22 dependence on initial  $\hat{\chi}_{NW}$  (slope of approximately -0.3 for both,  $R^2=0.92$  and  $0.98$  respectively)  
23  
24 whereas low imbibition Ca experimental data exhibits much lower dependence (slope of -0.12,  
25  
26  $R^2=0.37$ ). This suggests that fluid topology as described by  $\hat{\chi}$  plays a strong role in fluid  
27  
28 mobilization during flow dominated by viscous forces, but has reduced impact during capillary  
29  
30 dominated flow.  
31  
32  
33  
34  
35  
36  
37  
38

39 The relationship between residual trapping ( $S_R$ ) and initial NW  $\hat{\chi}$  illustrates these results  
40  
41 from a slightly different perspective (Figure 9); here a parabolic trend is evident for each  
42  
43 imbibition Ca category. Maximum residual NW saturation, i.e. the maximum trapping capacity  
44  
45 of the medium, is reached at a moderate initial  $\hat{\chi}_{NW}$  value ( $\hat{\chi}_{NW} \approx 0.4$ ) for both high ( $10^{-5.1}$ ) and  
46  
47 intermediate ( $10^{-6.6}$ ) Ca imbibition values, and trapping capacity is unaffected by the initial NW  
48  
49  $\hat{\chi}$  for low ( $10^{-8.6}$ ) Ca imbibition.

## 6.0 Conclusion and Application to CO<sub>2</sub> sequestration

This work has presented the results of x-ray CMT quantified experiments of drainage and imbibition with a wetting (W) phase of 1:6 by weight KI brine and nonwetting (NW) phase of air within Bentheimer sandstone. We have determined, based on a pore-scale force analysis, that capillary and viscous forces will dominate the system rather than gravity forces. We have shown experimentally that the residual state of the system is indeed sensitive to changes in capillary number (Ca), which describes the relative importance of capillary and viscous forces in a multiphase system. We have also investigated two different quantitative connectivity metrics and shown that NW phase trapping and mobilization is well described by the normalized Euler number of the NW phase ( $\hat{\chi}_{NW}$ ) after drainage: a more highly connected NW phase is connected by a high number of redundant pore throats, which allows for more NW phase to be mobilized, thus resulting in less NW phase capillary trapping. The dependence of capillary trapping on NW phase  $\hat{\chi}$  is more pronounced for systems in a viscosity dominated regime; for capillary-dominated systems (low Ca), the NW phase connectivity has less impact on the final NW trapping. This is consistent with standard understanding of displacement mechanisms: at sufficiently low flow rates the small pore throats that provide improved NW connectivity become water-filled by the process of “snap-off” early in the imbibition process; at higher flow rates snap-off is suppressed (e.g. [18]), so the connections through small pore throats remain open longer and therefore have a greater effect on the residual saturation. We note here that additional theoretical analysis is needed to completely describe the physics underlying the correlations between connectivity and capillary trapping.

Sedimentary reservoirs are proposed to be optimal storage sites for CO<sub>2</sub> sequestration due to the stratigraphy of porous, permeable sandstone and carbonate layers (which act as storage

1  
2  
3  
4 layers) and relatively impermeable silt and shale stone layers (which act as caprocks) [45, 46].  
5  
6 Given the range of supercritical CO<sub>2</sub> fluid properties attainable in a sequestration operation, and  
7  
8 in similar media to Bentheimer sandstone, the supercritical CO<sub>2</sub>-brine-sandstone system will be  
9  
10 dominated by capillary and viscous forces at the pore scale (Figure 2), and fall in the same  
11  
12 general area of the force balance plot as the air-brine-Bentheimer experiments presented here.  
13  
14 Thus, we expect that pore scale capillary trapping and mobilization of supercritical CO<sub>2</sub> during  
15  
16 sequestration to behave similarly to the air-brine-Bentheimer system examined here. Indeed,  
17  
18 Herring, et al. [11] found that micromodel studies of ambient-state NW phase invasion were able  
19  
20 to accurately predict the flow pattern of supercritical CO<sub>2</sub> during drainage in Bentheimer  
21  
22 sandstone by consideration and proper dimensional analysis of fluid properties.  
23  
24  
25  
26  
27  
28

29  
30 Comparison of Figure 4c with a typical Land's model curve (e.g. Al Mansoori et al. [2])  
31  
32 demonstrates that the plateau in NW S<sub>R</sub> values that is apparent above approximately 50% initial  
33  
34 NW saturation is due to the percolation threshold being exceeded during the drainage process.  
35  
36 Further, the data presented here shows that for a system at an initial NW saturation approaching  
37  
38 100% (and thus, maximum NW connectivity,  $\hat{\chi}_{NW} = 1.0$ ), capillary trapping is further  
39  
40 suppressed and NW S<sub>R</sub> actually decreases. This has important implications for CO<sub>2</sub> sequestration  
41  
42 operations, where high CO<sub>2</sub> saturations may exist near the injection site, and where dry-out  
43  
44 conditions may occur [47]. Dry-out occurs when CO<sub>2</sub> which is in chemical non-equilibrium with  
45  
46 brine is injected into the subsurface, causing the resident brine to dissolve into the CO<sub>2</sub> phase and  
47  
48 creating subsurface areas where NW phase saturation approaches 100%; if brine salinity is  
49  
50 sufficiently high, dry-out may cause salt precipitation leading to reduced permeability [47].  
51  
52  
53  
54  
55  
56

57 In the example of a geologic CO<sub>2</sub> sequestration operation, Figures 8a and 9 imply that  
58  
59 two distinct methodologies could be used to maximize capillary trapping, depending on the  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 desired result. To maximize capillary trapping *efficiency* ( $S_R/S_I$ ), and ensure that the largest  
5  
6 fraction of injected CO<sub>2</sub> is immobilized in the pore space of the reservoir, the CO<sub>2</sub> injection  
7  
8 should be engineered to result in low initial  $\hat{\chi}_{NW}$  (e.g. initial  $\hat{\chi}_{NW} \leq 0.1$ , or  $S_I \leq 0.75$ ). This  
9  
10 would provide for additional storage security beyond relying on a structural/stratigraphic  
11  
12 trapping layer. In contrast, in order to utilize the maximum trapping capacity of the pore space,  
13  
14 CO<sub>2</sub> injection should be engineered to result in moderate initial  $\hat{\chi}_{NW}$  (e.g.  $\hat{\chi}_{NW} = 0.4$ , or  $S_I \approx$   
15  
16 0.85). For either goal, dry-out conditions should be avoided. Manipulation of initial  $\hat{\chi}_{NW}$  could  
17  
18 potentially be accomplished via use of a water-alternating-gas scheme (as proposed by Spiteri et  
19  
20 al. [48]), which may have significant water use impacts; or via manipulation of injection patterns  
21  
22 to inject to intermediate saturations. For example, one suggestion would be to have a shorter  
23  
24 vertical injection interval in the injection well: injection only into the lower portions of the  
25  
26 aquifer would allow for vertical migration and might prevent the CO<sub>2</sub> plume from approaching  
27  
28 high saturation levels at the injection point. Alternatively, the subsequent imbibition process  
29  
30 should be carried out at very low Ca regime, where NW topology does not impact residual  
31  
32 saturation or capillary trapping efficiency. Manipulation of far-from-wellbore saturation can be  
33  
34 achieved for well-characterized aquifers by designing the injection program in conjunction with  
35  
36 large-scale simulation.

## Figures

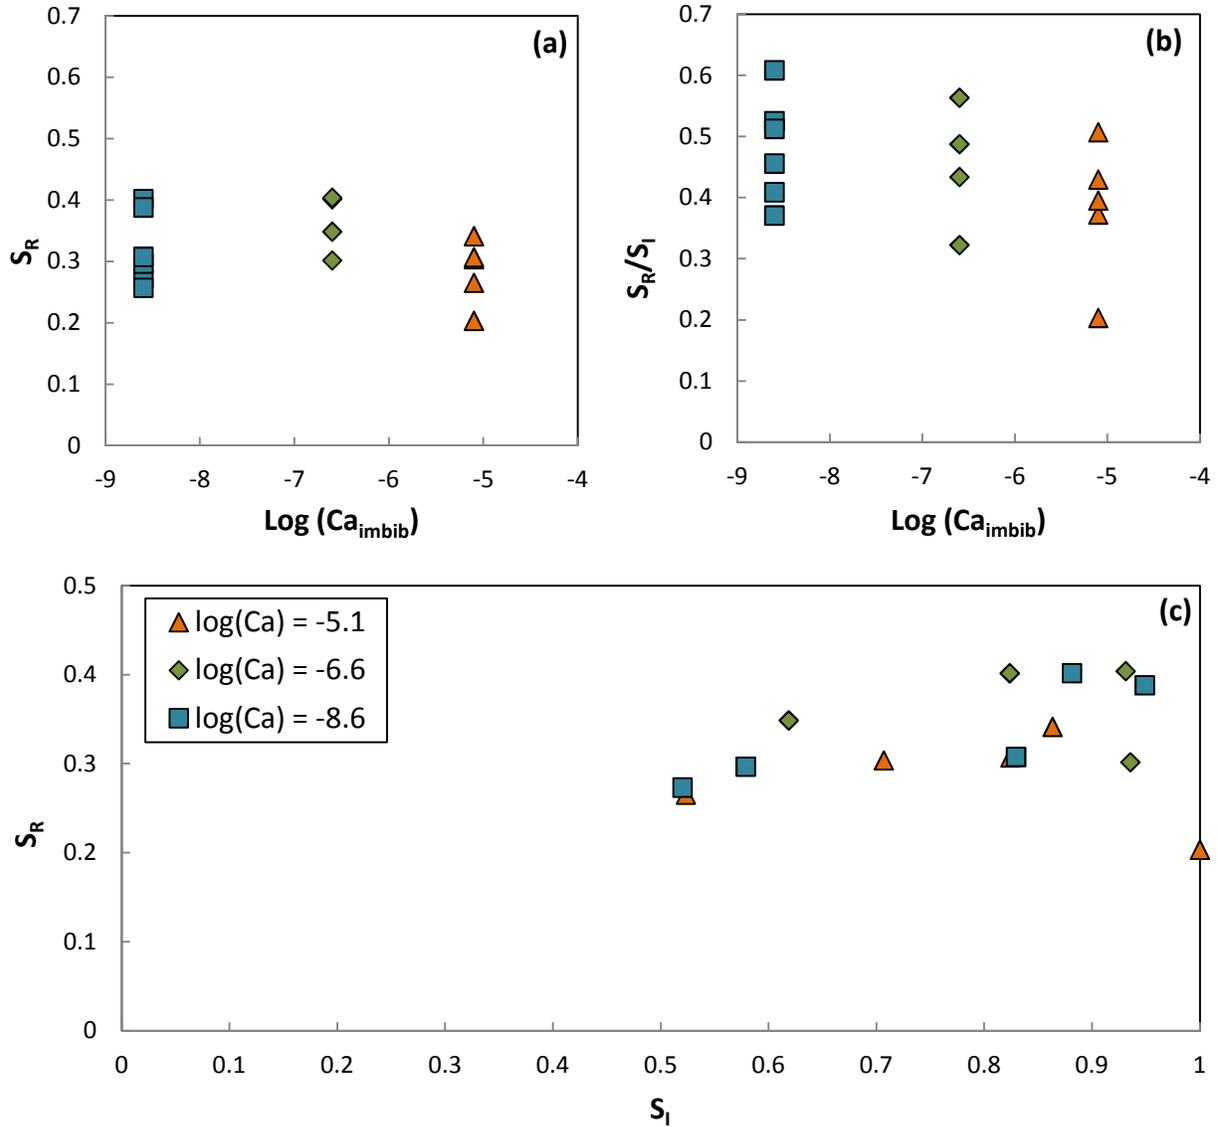

**Figure 1.** Capillary trapped residual nonwetting (NW) phase saturation ( $S_R$ ) as a function of imbibition capillary number ( $Ca_{imbib}$ ), modified from Cense and Berg [1].

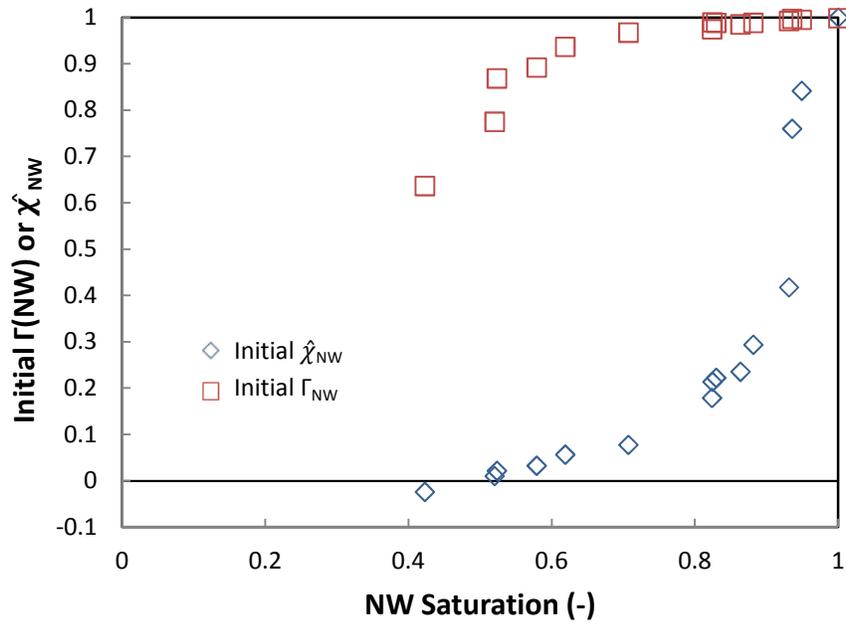

**Figure 2.** The locations of imbibition processes of previous works, the experiments of this study, and an approximate range for supercritical CO<sub>2</sub> sequestration (red rhomboid) within the pore scale force balance. Inverse Bond number ( $Bo^{-1}$ ) describes the balance between capillary and gravity forces, and the product of capillary number ( $Ca$ ) and  $Bo^{-1}$  describes the balance between viscosity and gravity forces.

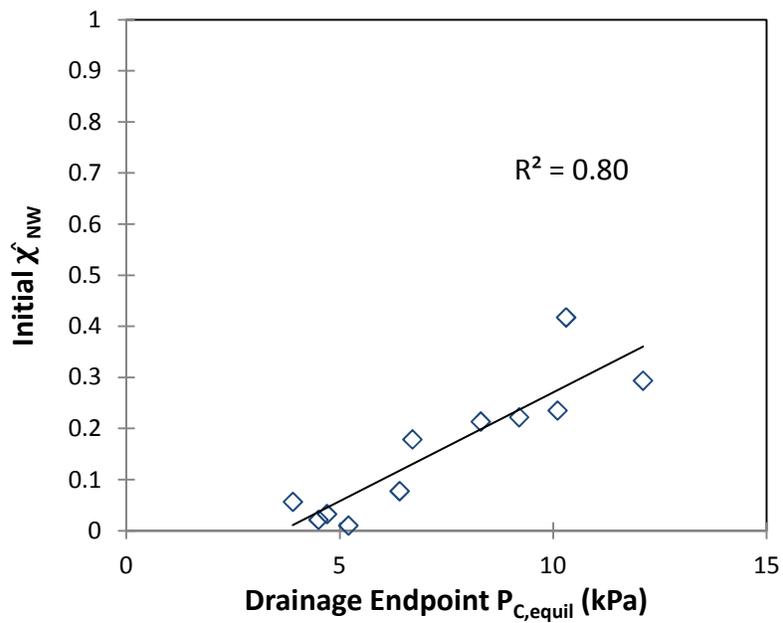

**Figure 3.** A cross-sectional slice of (a) raw data, (b) data after application of a three-dimensional (3D) median filter, and (c) binary data with the nonwetting (NW) phase identified. The grayscale histogram of the data volume for both raw and 3D median-filtered data is shown in (d) with the grayscale threshold value indicated.

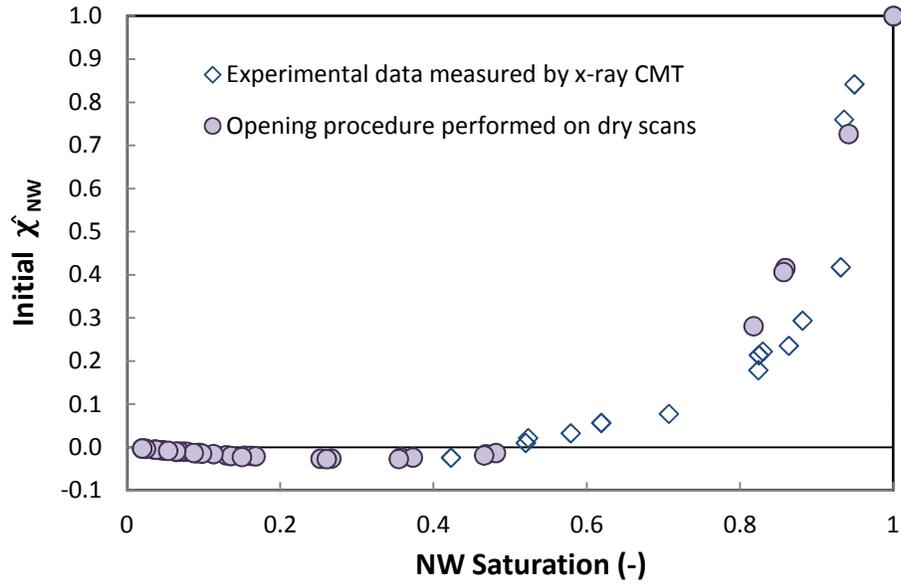

**Figure 4.** Results of drainage-imbibition experiments presented as (a) residual saturation ( $S_R$ ) as a function of imbibition capillary number ( $Ca_{\text{imbib}}$ ); (b) trapping efficiency, calculated as residual saturation normalized by initial saturation ( $S_I$ ), as a function of imbibition  $Ca$ ; and (c) residual saturation as a function of initial saturation (i.e. the traditional Land's model formulation [3, 31]) where experiments are classified by the imbibition  $Ca$  class as noted in the legend.

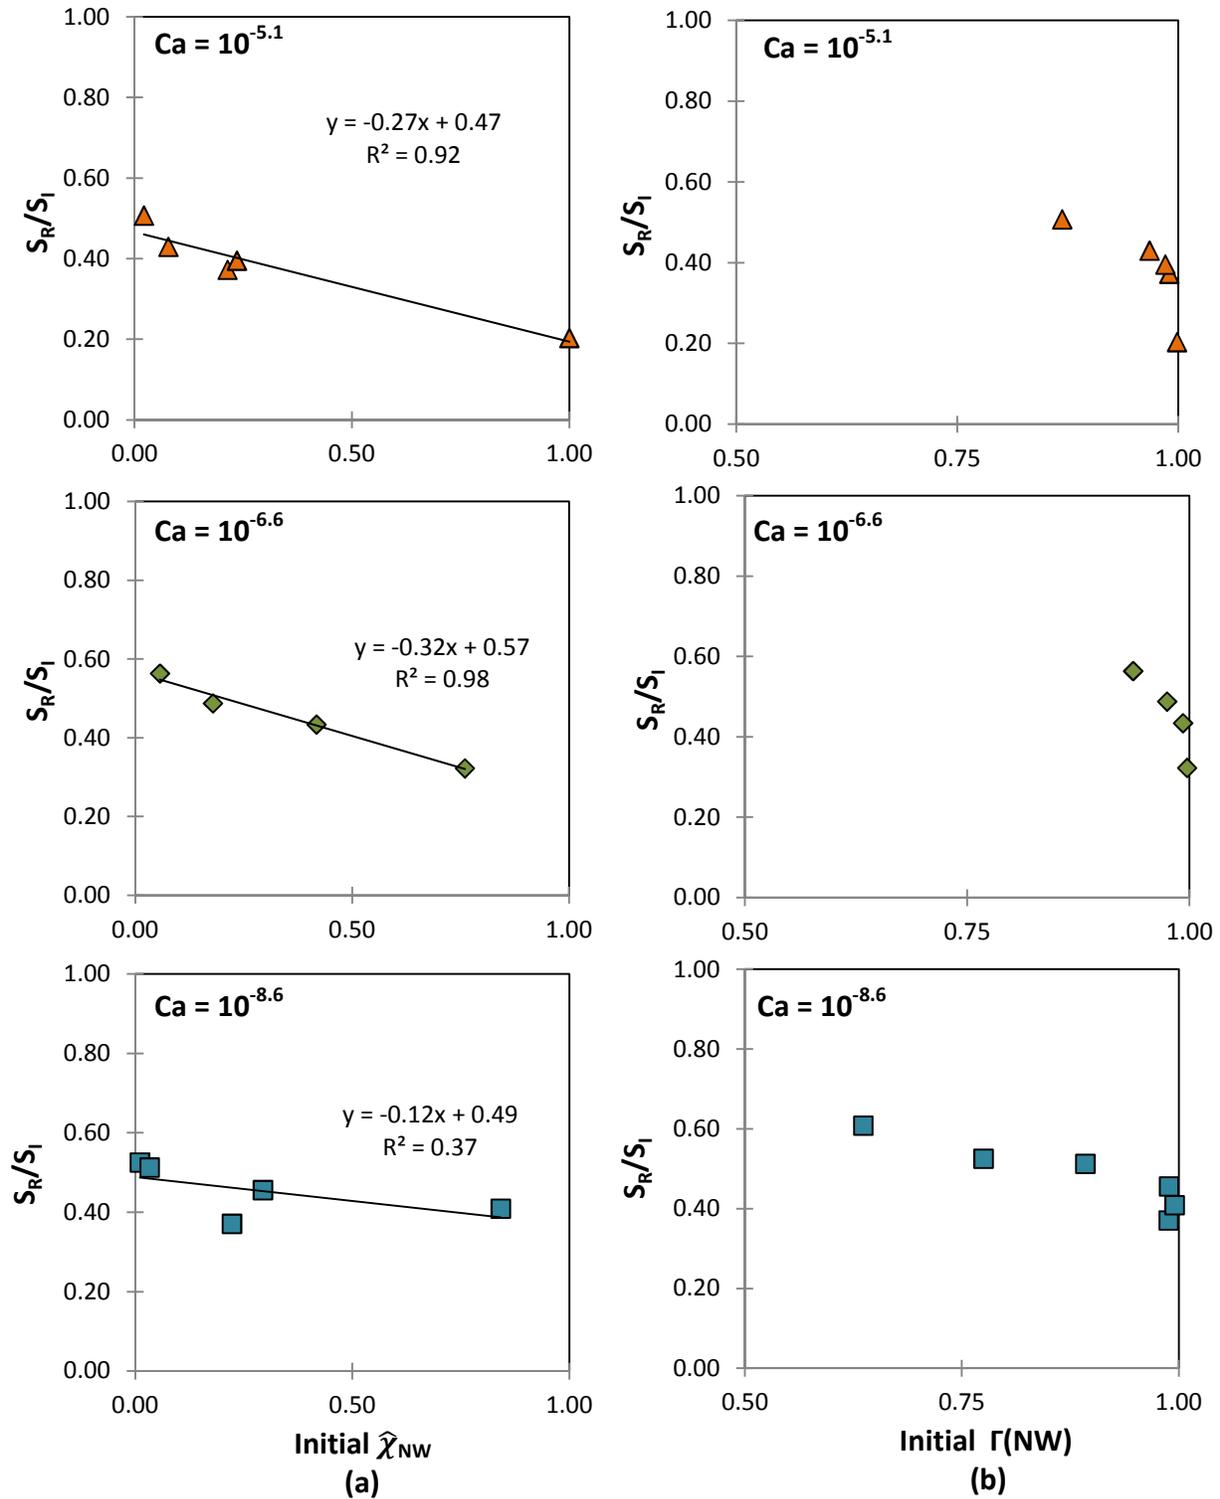

**Figure 5.** Connectivity of nonwetting (NW) phase at the initial system state as measured by  $\Gamma(\text{NW})$  and initial normalized Euler value ( $\hat{\chi}_{\text{NW}}$ ) as a function of NW saturation within Bentheimer sandstone.

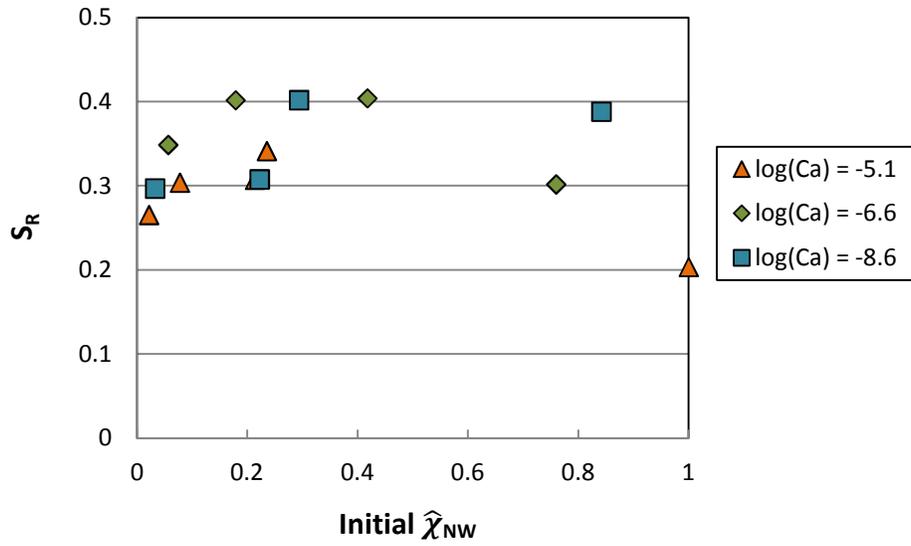

**Figure 6.** Initial nonwetting (NW) normalized Euler value ( $\hat{\chi}_{\text{NW}}$ ) versus capillary pressure ( $P_C$ ) after an equilibration period at the end of the drainage process within Bentheimer sandstone.

**Figure 7.** Initial nonwetting (NW) normalized Euler value ( $\hat{\chi}_{NW}$ ) as a function of NW saturation within Bentheimer sandstone for experimental x-ray microtomography (x-ray CMT) data and for a computational morphological opening process performed on binary data of the dry sandstone.

**Figure 8.** Capillary trapping efficiency of nonwetting (NW) phase, as described by residual NW saturation ( $S_R$ ) normalized by initial NW saturation ( $S_I$ ), as a function of (a) normalized initial NW Euler value (initial  $\hat{\chi}_{NW}$ ) and (b) initial  $\Gamma(NW)$ . Data are classified by the experimental imbibition capillary number ( $Ca$ ).

**Figure 9.** Residual capillary trapped nonwetting (NW) phase ( $S_R$ ) as a function of normalized initial NW Euler value (Initial  $\hat{\chi}_{NW}$ ). Data are classified by the experimental imbibition capillary number ( $Ca$ ).
